Problem Solving: Informed (Heuristic) Search

**Uninformed (blind)** search algorithms can find an (optimal) solution to the problem, but they are usually not very efficient.

- BFS, DFS, ID, BiS

**Informed (heuristic)** search algorithms can find solutions more efficiently thanks to exploiting problem-specific knowledge.

#### – How to use heuristics in search?

• BestFS, A\*, IDA\*, RBFS, SMA\*

#### – How to construct heuristics?

• relaxation, pattern databases

Recall that we are looking for (the shortest) path from the initial state to some goal state.

Which information can help the search algorithm?

- For example, the length of path to some goal state.
- However such information is usually not available (if it is available then we do not need to do search). Usually some **evaluation function f(n)** is used to evaluate "quality" of node **n** based on the length of path to the goal.
- best-first search
  - The node with the smallest value of f(n) is used for expansion.
- There are search algorithms with different views of f(n). Usually the part of f(n) is a heuristic function h(n) estimating the length of the shortest (cheapest) path to the goal state.
  - Heuristic functions are the most common form of additional information given to search algorithms
  - We will assume that  $h(n) = 0 \Leftrightarrow n$  is goal.

### Let us try to expand first the node that is closest to some goal state, i.e. f(n) = h(n).

#### greedy best-first search algorithm

#### **Example** (path Arad $\rightarrow$ Bucharest):

- We have a table of direct distances from any city to Bucharest.
- Note: this information was not part of the original problem formulation!

#### We already know that the greedy algorithm **may not find the optimal path**.

#### **Can we at least guarantee finding some path?**

- If we expand first the node with the smallest cost then the (tree search) algorithm may not find any solution.
   Example: path Iasi → Fagaras
  - Go to Neamt, then back to Iasi, Neamt, ...
  - We need to detect repeated visits in cities!

- Time complexity O(b<sup>m</sup>), where m is the maximal depth
- Memory complexity O(b<sup>m</sup>)
- A good heuristic function can significantly decrease the practical complexity.

### Let us now try to use f(n) = g(n) + h(n)

- recall that g(n) is the cost of path from root to n
- probably the most popular heuristic search algorithm
- f(n) represents the cost of path through n
- the algorithm does not extend already long paths

:(n.a.n'

#### What about completeness and optimality of A\*?

First a few definitions:

- admissible heuristic h(n)
  - h(n) ≤ "the cost of the cheapest path from n to goal"
  - an optimistic view (the algorithm assumes a better cost than the real cost)
  - function f(n) in A\* is a lower estimate of the cost of path through n
- monotonous (consistent) heuristic h(n) nemies sites of nemoin
  - let **n**' be a successor of **n** via action **a** and **c(n,a,n')** be the transition cost
  - $h(n) \leq c(n,a,n') + h(n')$   $h(n) h(n') \leq c(n,a,n')$
  - this is a form of triangle inequality

#### Monotonous heuristic is admissible.

let  $n_1$ ,  $n_2$ ,...,  $n_k$  be the optimal path from  $\mathbf{n_1}$  to goal  $\mathbf{n_k}$ , then  $h(n_i) - h(n_{i+1}) \le c(n_i, a_i, n_{i+1})$ , via monotony  $h(n_1) \le \Sigma_{i=1,..,k-1} c(n_i, a_i, n_{i+1})$ , after "sum" - Leshopich' Sum

### For a monotonous heuristic the values of f(n) are non-decreasing over any path.

Let **n'** be a successor of **n**, i.e. g(n') = g(n) + c(n,a,n'), then  $f(n') = g(n') + h(n') = g(n) + c(n,a,n') + h(n') \ge g(n) + h(n) = f(n)$ 

#### Algorithm A\*: optimality

### If h(n) is an admissible heuristic then the algorithm A\* in TREE-SEARCH is optimal.

- in other words the first expanded goal is optimal
- Let  $G_2$  be sub-optimal goal from the fringe and C\* be the optimal cost
  - $f(G_2) = g(G_2) + h(G_2) = g(G_2) > C^*$ , because  $h(G_2) = 0$
- Let **n** be a node from the fringe and being on the optimal path
  - $f(n) = g(n) + h(n) \le C^*$ , via admissibility of h(n)
- together

•  $f(n) \le C^* < f(G_2)$ ,

i.e., the algorithm must expand  $\mathbf{n}$  before  $G_2$  and this way it finds the optimal path.

### If h(n) is a monotonous heuristic then the algorithm A\* in GRAPH-SEARCH is optimal.

- Possible **problem**: reaching the same state for the second time using a better path classical GRAPH-SEARCH ignores this second path!
- Possible **solution**: selection of the better of the two paths leading to the closed node (extra bookkeeping) or using monotonous heuristic.
  - for monotonous heuristics, the values of f(n) are non-decreasing over any path
  - A\* selects for expansion the node with the smallest value of f(n), i.e., the values f(m) of other open nodes m are not smaller, i.e., among all "open" paths to n there cannot be a shorter path than the path just selected (no path can shorten)
  - hence, the first closed goal node is optimal

m

<? a

#### Algorithm A\*: properties

For non-decreasing function f(n) we can draw **contours** in the state graph (the nodes inside a given contour have f-costs less than or equal to the contour value.

- for h(n) = 0 we obtain circles around the start
- for more accurate h(n) we use, the bands will stretch toward the goal state and become more narrowly focused around the optimal path.

- A\* expands all nodes such that f(n) < C\* on the contour</p>
- $A^*$  can expand some nodes such that  $f(n) = C^*$
- the nodes **n** such that  $f(n) > C^*$  are never expanded
- the algorithm A\* is **optimally efficient** for any given consistent heuristic

- **Time complexity:** A\* can expand an exponential number of nodes
  - this can be avoided if  $|h(n)-h^*(n)| \le O(\log h^*(n))$ , where  $h^*(n)$  is the cost of optimal path from n to goal \_\_\_\_

**Space complexity:** A\* keeps in memory all expanded nodes

A\* usually runs out of space long before it runs out of time

#### Iterative-deepening A\*

## A simple way to decrease memory consumption is iterative deepening.

#### **Algorithm IDA\***

function IDA\*(problem) returns a solution sequence
inputs: problem, a problem
static: f-limit, the current f- COST limit
root, a node

root ← MAKE-NODE(INITIAL-STATE[problem]) f-limit ← f- COST(root) loop do solution, f-limit ← DFS-CONTOUR(root, f-limit) if solution is non-null then return solution if f-limit = ∞ then return failure; end

**function** DFS-CONTOUR(*node*, *f*-*limit*) **returns** a solution sequence and a new *f*- COST limit **inputs**: *node*, a node *f*-*limit*, the current *f*- COST limit **static**: *next-f*, the *f*- COST limit for the next contour, initially  $\infty$ 

if f- COST[node] > f-limit then return null, f- COST[node]
if GOAL-TEST[problem](STATE[node]) then return node, f-limit
for each node s in SUCCESSORS(node) do
 solution, new-f ← DFS-CONTOUR(s, f-limit)
 if solution is non-null then return solution, f-limit
 next-f ← MIN(next-f, new-f); end
return null, next-f

- the search limit is defined using the cost
   f(n) instead of depth
- for the next iteration we use the smallest value
   f(n) of node n that exceeded the limit in the last iteration
- frequently used algorithm

#### Recursive best-first search

Let us try to mimic standard best-first search, but using only linear space

- the algorithm stops exploration if there is an alternative path with better cost f(n)
- when the algorithm goes back to node n, it replaces the value f(n) using the cost of successors (remembers the best leaf in the forgotten subtree)

#### If h(n) is an admissible heuristic then the algorithm is optimal.

- Space complexity O(bd)
- Time complexity is still exponential (suffers from excessive node re-generation) furt define to co best-first-search, ponce to silvane fringe.

```
function RECURSIVE-BEST-FIRST-SEARCH(problem) returns a solution, or failure

RBFS(problem, MAKE-NODE(INITIAL-STATE[problem]), \infty)

function RBFS(problem, node, f_limit) returns a solution, or failure and a new f-cost limit

if GOAL-TEST[problem](STATE[node]) then return node

successors \leftarrow EXPAND(node, problem)

if successors is empty then return failure, \infty

for each s in successors do

f[s] \leftarrow \max(g(s) + h(s), f[node])

repeat

best \leftarrow the lowest f-value node in successors

if f[best] > f_{limit} then return failure, f[best]

alternative \leftarrow the second-lowest f-value among successors

result, f[best] \leftarrow RBFS(problem, best, \min(f_{limit}, alternative))

if result \neq failure then return result
```

#### *Recursive BFS: example*

#### IDA\* and RBFS do not exploit available memory! This is a pity as the already expanded nodes are reexpanded again (waste of time) Let us try to modify classical A\*

- when memory is full, drop the worst leaf node – the node with the highest f-value (if there are more such nodes then drop the shallowest node)
- similarly to RBFS back up the value of the forgotten node to its parent

#### Simplified memory-bounded A\*: example

#### furt à vorigin, jané jseus mé min. Modrocení

- Assume memory for three nodes only.
- If there is enough memory to store an optimal path then SMA\* finds an optimal solution.
- Otherwise it finds the best path with available memory.
  - If the cost of J would be 19, then this is optimal goal, but the path to it can not be stored in memory!

> pali mužn něleterí cesto obodnotit dráč juh realina cesta

A\* still expands a lot of nodes (to guarantee optimality). If we are willing to accept suboptimal solutions (good enough or **satisficing solutions**), we can explore fewer nodes.

How? We allow inadmissible heuristics.

#### Weighted A\*

**f(n) = g(n) + W** × **h(n)**, for some W > 1

Finds solutions with the cost between C\* and W x C\* (in practice, the cost is closer to C\* than to W x C\*).  $A^*$ 

| Algorithm                | f(n)                   | W            |
|--------------------------|------------------------|--------------|
| A* search                | g(n) + h(n)            | W = 1        |
| Uniform-cost search      | g(n)                   | W = 0        |
| Greedy best-first search | h(n)                   | $W = \infty$ |
| Weighted A* search       | $g(n) + W \times h(n)$ | 1 < W < ∞    |

Weighted A\*

7 times fewer states 5% mostly costly path

#### Looking for heuristics

#### How to find admissible heuristics?

#### Example: 8-puzzle

- 22 steps to goal in average
- branching factor around 3

Start State

Goal State

- (complete) search tree:  $3^{22} \approx 3, 1 \times 10^{10}$  nodes
- the number of reachable states is only 9!/2 = 181440
- for 15-puzzle there are 10<sup>13</sup> states
- we need some heuristic, preferable admissible
  - $-h_1 = "the number of misplaced tiles"$ = 8
  - $-h_2 =$ *"*the sum of the distances of the tiles from the goal positions"

= 3 + 1 + 2 + 2 + 2 + 3 + 3 + 2 = 18

a so called Manhattan heuristic

the optimal solution needs 26 steps

#### How to characterize the quality of a heuristic? Effective branching factor b\*

- Let the algorithm need N nodes to find a solution in depth d \_\_\_\_\_ Hable je neco, co empiricity /experimentallue zjishim
- b\* is a branching factor of a uniform tree of depth d containing N+1 nodes
  Null = 1 + b\* + (b\*)<sup>2</sup>

 $N+1 = 1 + b^* + (b^*)^2 + ... + (b^*)^d$ 

#### **Example:**

- 8-puzzle
- the average over 100 instances for each of various solution lengths

|    | Sea    | arch Cost (nodes g      | enerated)  | Effective Branching Factor |            |                       |  |
|----|--------|-------------------------|------------|----------------------------|------------|-----------------------|--|
| d  | BFS    | $\mathbf{A}^{*}(h_{1})$ | $A^*(h_2)$ | BFS                        | $A^*(h_1)$ | $\mathbf{A}^{*}(h_2)$ |  |
| 6  | 128    | 24                      | 19         | 2.01                       | 1.42       | 1.34                  |  |
| 8  | 368    | 48                      | 31         | 1.91                       | 1.40       | 1.30                  |  |
| 10 | 1033   | 116                     | 48         | 1.85                       | 1.43       | 1.27                  |  |
| 12 | 2672   | 279                     | 84         | 1.80                       | 1.45       | 1.28                  |  |
| 14 | 6783   | 678                     | 174        | 1.77                       | 1.47       | 1.31                  |  |
| 16 | 17270  | 1683                    | 364        | 1.74                       | 1.48       | 1.32                  |  |
| 18 | 41558  | 4102                    | 751        | 1.72                       | 1.49       | 1.34                  |  |
| 20 | 91493  | 9905                    | 1318       | 1.69                       | 1.50       | 1.34                  |  |
| 22 | 175921 | 22955                   | 2548       | 1.66                       | 1.50       | 1.34                  |  |
| 24 | 290082 | 53039                   | 5733       | 1.62                       | 1.50       | 1.36                  |  |
| 26 | 395355 | 110372                  | 10080      | 1.58                       | 1.50       | 1.35                  |  |
| 28 | 463234 | 202565                  | 22055      | 1.53                       | 1.49       | 1.36                  |  |

## Is h<sub>2</sub> (from 8-puzzle) always better than h<sub>1</sub> and how to recognize it?

- notice that  $\forall n h_2(n) \ge h_1(n)$
- we say that **h**<sub>2</sub> **dominates h**<sub>1</sub>
- A\* with  $h_2$  never expands more nodes than A\* with  $h_1$ 
  - A\* expands all nodes such that f(n) < C\*, so h(n) < C\* g(n)</li>
  - In particular if it expands a node using h<sub>2</sub>, then the same node must be expanded using h<sub>1</sub>

### It is always better to use a heuristic function giving higher values provided that

- the limit C\* g(n) is not exceeded (then the heuristic would not be admissible)
- the computation time is not too long

Chai, any /h(n) - (C\*-g(n)) / hyl conejmensi -> tedy droi uprot nejvice dominipión strategii

### Can an agent construct admissible heuristics for any problem?

#### Yes, via **problem relaxation**!

- relaxation is a simplification of the problem such that the solution of the original problem is also a solution of the relaxed problem (even if not necessarily optimal)
- we need to be able to solve the relaxed problem fast
- the cost of optimal solution to a relaxed problem is a lower bound for the solution to the original problem and hence it is an admissible (and monotonous) heuristic for the original problem

#### Example (8-puzzle) C(relaxed) = C (original), tahir to la parit jubo hemistika

- a tile can move from square A to square B if:
  - A is horizontally or vertically adjacent to B
  - B is blank
- possible relaxations (omitting some constraints to move a tile):
  - a tile can move from square A to square B if A is adjacent to B (Manhattan distance) - mize hyber Osmi shey misto h.
  - a tile can move from square A to square B if B is blank
  - a tile can move from square A to square B (heuristic h<sub>1</sub>)

### Another approach to admissible heuristics is using a **pattern database**

- based on solution of specific sub-problems (patterns)
- by searching back from the goal and recording the cost of each new **pattern** encountered

- heuristic is defined by taking
   the worst cost of a pattern that matches the current state
- Beware! The "sum" of costs of matching patterns needs not be admissible (the steps for solving one pattern may be used when solving another pattern).
- If there are **more heuristics**, we can always use the **maximum** value from them (such a heuristic dominates each of the used heuristics).

-ngric dominning hunistihu...
