unless otherwise stated

Given a collection of random variables  $\mathbf{x}_1, \dots, \mathbf{x}_N$ , we know that

$$\mathbb{E} \left[ \sum_i \mathbf{x}_i \right] = \sum_i \mathbb{E} [\mathbf{x}_i].$$

But how about  $\text{Var} \left( \sum_i \mathbf{x}_i \right)$ ?

$$\begin{aligned} \text{Var} \left( \sum_i \mathbf{x}_i \right) &= \mathbb{E} \left[ \left( \sum_i \mathbf{x}_i - \sum_i \mathbb{E}[\mathbf{x}_i] \right)^2 \right] \\ &= \mathbb{E} \left[ \left( \sum_i (\mathbf{x}_i - \mathbb{E}[\mathbf{x}_i]) \right)^2 \right] \\ &= \mathbb{E} \left[ \sum_i \sum_j (\mathbf{x}_i - \mathbb{E}[\mathbf{x}_i]) (\mathbf{x}_j - \mathbb{E}[\mathbf{x}_j]) \right] \\ &= \sum_i \sum_j \mathbb{E} \left[ (\mathbf{x}_i - \mathbb{E}[\mathbf{x}_i]) (\mathbf{x}_j - \mathbb{E}[\mathbf{x}_j]) \right]. \end{aligned}$$

We define **covariance** of two random variables  $x, y$  as

$$\text{Cov}(x, y) = \mathbb{E} \left[ (x - \mathbb{E}[x]) (y - \mathbb{E}[y]) \right].$$

Then,

$$\text{Var}(x) = \mathbb{E}(x^2) - \mathbb{E}(x)^2$$

$$\text{Var} \left( \sum_i x_i \right) = \sum_i \sum_j \text{Cov}(x_i, x_j).$$

Note that  $\text{Cov}(x, x) = \text{Var}(x)$  and that we can write covariance as

$$\begin{aligned} \text{Cov}(x, y) &= \mathbb{E} \left[ (x - \mathbb{E}[x]) (y - \mathbb{E}[y]) \right] \\ &= \mathbb{E} \left[ xy - x\mathbb{E}[y] - \mathbb{E}[x]y + \mathbb{E}[x]\mathbb{E}[y] \right] \\ &= \mathbb{E} [xy] - \mathbb{E}[x]\mathbb{E}[y]. \end{aligned}$$

*algebraisch*

Two random variables  $x, y$  are **uncorrelated** if  $\text{Cov}(x, y) = 0$ ; otherwise, they are **correlated**.

Note that two *independent* random variables are uncorrelated, because

$$\begin{aligned}
 \text{Cov}(x, y) &= \mathbb{E} \left[ (x - \mathbb{E}[x]) (y - \mathbb{E}[y]) \right] \\
 &= \sum_{x,y} P(x, y) (x - \mathbb{E}[x]) (y - \mathbb{E}[y]) \\
 &= \sum_{x,y} P(x) (x - \mathbb{E}[x]) P(y) (y - \mathbb{E}[y]) \quad \text{---} \rightarrow \text{díky nezávislosti můžeme rozpučkovat} \\
 &= \sum_x P(x) (x - \mathbb{E}[x]) \sum_y P(y) (y - \mathbb{E}[y]) \\
 &= \mathbb{E}_x [x - \mathbb{E}[x]] \mathbb{E}_y [y - \mathbb{E}[y]] \quad \text{---} \rightarrow \mathbb{E}(\mathbb{E}(y)) = \mathbb{E}(y) \\
 &= \mathbb{E}_x [x - \mathbb{E}[x]] \cdot \mathbb{E}_y [y - \mathbb{E}[y]] = 0 \cdot 0 = 0
 \end{aligned}$$

However, dependent random variables can be uncorrelated – random uniform  $x$  on  $[-1, 1]$  and  $y = |x|$  are not independent ( $y$  is completely determined by  $x$ ), but they are uncorrelated.

# Pearson correlation coefficient

There are several ways to measure correlation of random variables  $x, y$ .

**Pearson correlation coefficient**, denoted as  $\rho$  or  $r$ , is defined as

$$\rho \stackrel{\text{def}}{=} \frac{\text{Cov}(x, y)}{\sqrt{\text{Var}(x)} \sqrt{\text{Var}(y)}} \quad \text{ditte formule to zeker } \in [-1, 1]$$

$$r \stackrel{\text{def}}{=} \frac{\sum_i (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_i (x_i - \bar{x})^2} \sqrt{\sum_i (y_i - \bar{y})^2}},$$

where:

- $\rho$  is used when the full expectation is computed (population Pearson correlation coefficient);
- $r$  is used when estimating the coefficient from data (sample Pearson correlation coefficient);
  - $\bar{x}$  and  $\bar{y}$  are sample estimates of the respective means.

# Pearson correlation coefficient

The value of Pearson correlation coefficient is in fact normalized covariance, because its value is always bounded by  $-1 \leq \rho \leq 1$  (and the same holds for  $r$ ).

The bound can be derived from

$$\begin{aligned}
 0 &\leq \mathbb{E} \left[ \left( \frac{(x - \mathbb{E}[x])}{\sqrt{\text{Var}(x)}} - \rho \frac{(y - \mathbb{E}[y])}{\sqrt{\text{Var}(y)}} \right)^2 \right] \\
 &= \mathbb{E} \left[ \frac{(x - \mathbb{E}[x])^2}{\text{Var}(x)} \right] - 2\rho \mathbb{E} \left[ \frac{(x - \mathbb{E}[x])}{\sqrt{\text{Var}(x)}} \frac{(y - \mathbb{E}[y])}{\sqrt{\text{Var}(y)}} \right] + \rho^2 \mathbb{E} \left[ \frac{(y - \mathbb{E}[y])^2}{\text{Var}(y)} \right] \\
 &= \frac{\text{Var}(x)}{\text{Var}(x)} - 2\rho \cdot \rho + \rho^2 \frac{\text{Var}(y)}{\text{Var}(y)} = 1 - \rho^2,
 \end{aligned}$$

which yields  $\rho^2 \leq 1$ .

Alternatively, the desired inequality can be obtained by applying the Cauchy-Schwarz inequality  $\langle u, v \rangle \leq \sqrt{\langle u, u \rangle} \sqrt{\langle v, v \rangle}$  on  $\langle x, y \rangle \stackrel{\text{def}}{=} \mathbb{E}[xy]$ .

# Pearson correlation coefficient

Pearson correlation coefficient quantifies **linear dependence** of the two random variables.

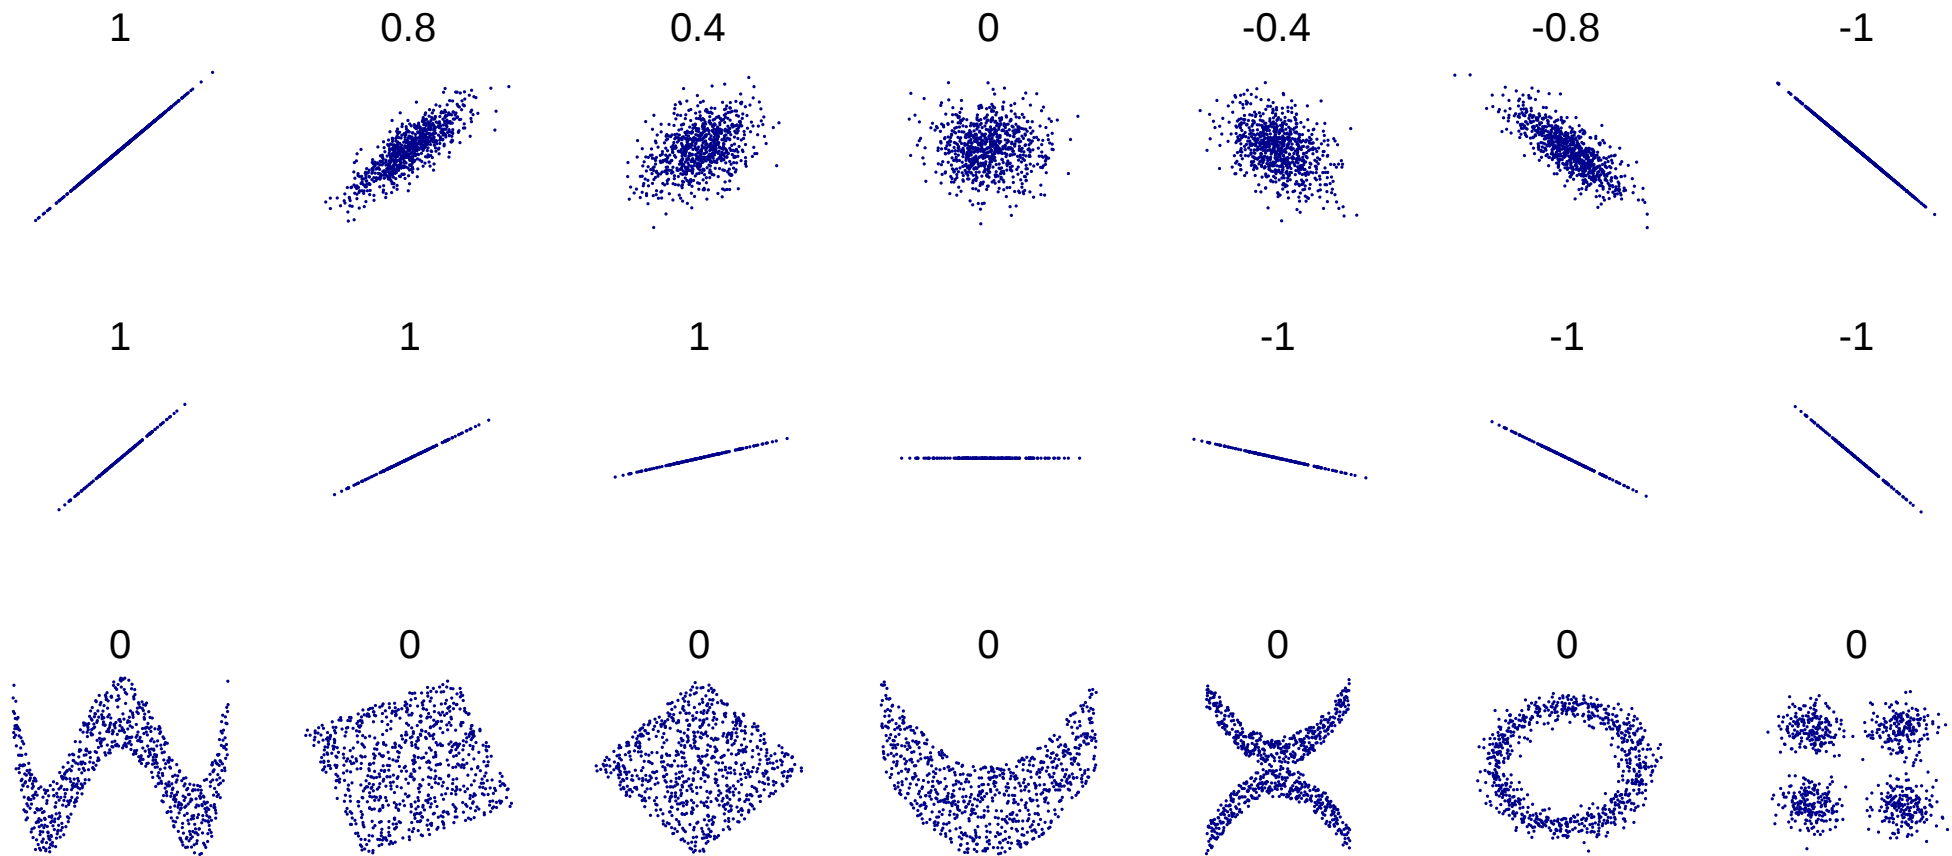

*Pozor,  
je jedno jak moc  
to klesá. Jen jsou  
prostě přímo na přímce.*

[https://upload.wikimedia.org/wikipedia/commons/3/34/Correlation\\_coefficient.png](https://upload.wikimedia.org/wikipedia/commons/3/34/Correlation_coefficient.png)

# Pearson correlation coefficient

Pearson correlation coefficient quantifies **linear dependence** of the two random variables.

[https://upload.wikimedia.org/wikipedia/commons/d/d4/Correlation\\_examples2.svg](https://upload.wikimedia.org/wikipedia/commons/d/d4/Correlation_examples2.svg)

# Pearson correlation coefficient

The four displayed variables have the same mean 7.5, variance 4.12, Pearson correlation coefficient 0.816 and regression line  $3 + \frac{1}{2}x$ .

[https://upload.wikimedia.org/wikipedia/commons/e/ec/Anscombe%27s\\_quartet\\_3.svg](https://upload.wikimedia.org/wikipedia/commons/e/ec/Anscombe%27s_quartet_3.svg)

# Nonlinear Correlation – Spearman's $\rho$

To measure also nonlinear correlation, two coefficients are commonly used.

## Spearman's rank correlation coefficient $\rho$

Spearman's  $\rho$  is Pearson correlation coefficient measured on **ranks** of the original data, where a rank of an element is its index in sorted ascending order.

*Občas je těžké vidět, co to vlastně rank index*

[https://upload.wikimedia.org/wikipedia/commons/4/4e/Spearman\\_fig{1,2,3,5,4}.svg](https://upload.wikimedia.org/wikipedia/commons/4/4e/Spearman_fig{1,2,3,5,4}.svg)

*setřídím podle x, pak podle y*

## Kendall rank correlation coefficient $\tau$

Kendall's  $\tau$  measures the amount of *concordant pairs* (pairs where  $y$  increases/decreases when  $x$  does), minus the *discordant pairs* (where  $y$  increases/decreases when  $x$  does the opposite):

$$\tau \stackrel{\text{def}}{=} \frac{|\{\text{pairs } i \neq j : x_j > x_i, y_j > y_i\}| - |\{\text{pairs } i \neq j : x_j > x_i, y_j < y_i\}|}{\binom{n}{2}}$$

$$= \frac{\sum_{i < j} \text{sign}(x_j - x_i) \text{sign}(y_j - y_i)}{\binom{n}{2}}$$

$y_i < ? > y_j$   
 $x_i < x_j$   
 tech je max  $\binom{n}{2}$ ,  
 proto pristupujeme a  $\in (-1, 1)$

There is no clear consensus whether to use Spearman's  $\rho$  or Kendall's  $\tau$ . When there are no/few ties in the data, Kendall's  $\tau$  offers two minor advantages –  $\frac{1+\tau}{2}$  can be interpreted as a probability of a concordant pair, and Kendall's  $\tau$  converges to a normal distribution faster.

As defined, the range of Kendall's  $\tau \in [-1, 1]$ . However, if there are ties, its range is smaller – therefore, several corrections (not discussed here) exist to adjust its value in case of ties.

# Usage of Correlation in Machine Learning

In the machine learning area, correlation is commonly used to measure “agreement” between:

- several human annotations;
- automatic metric and gold annotation;

Figure 4.4 of diploma thesis "Adaptive Handwritten Text Recognition", <https://hdl.handle.net/20.500.11956/147680>

- automatic metric and human evaluation.

*Či už hledím metriku (nebo třeba jen parametr  $\beta$  u F-score), kterí bude nejlépe reflektovat, co člověk chce*

*Tedy v tomto případě měl člověk 2x více precision než recall.*

The goal of **ensembling** is to combine several models in order to reach higher performance.

The simplest approach is to train several independent models and then to combine their predictions by averaging or voting.

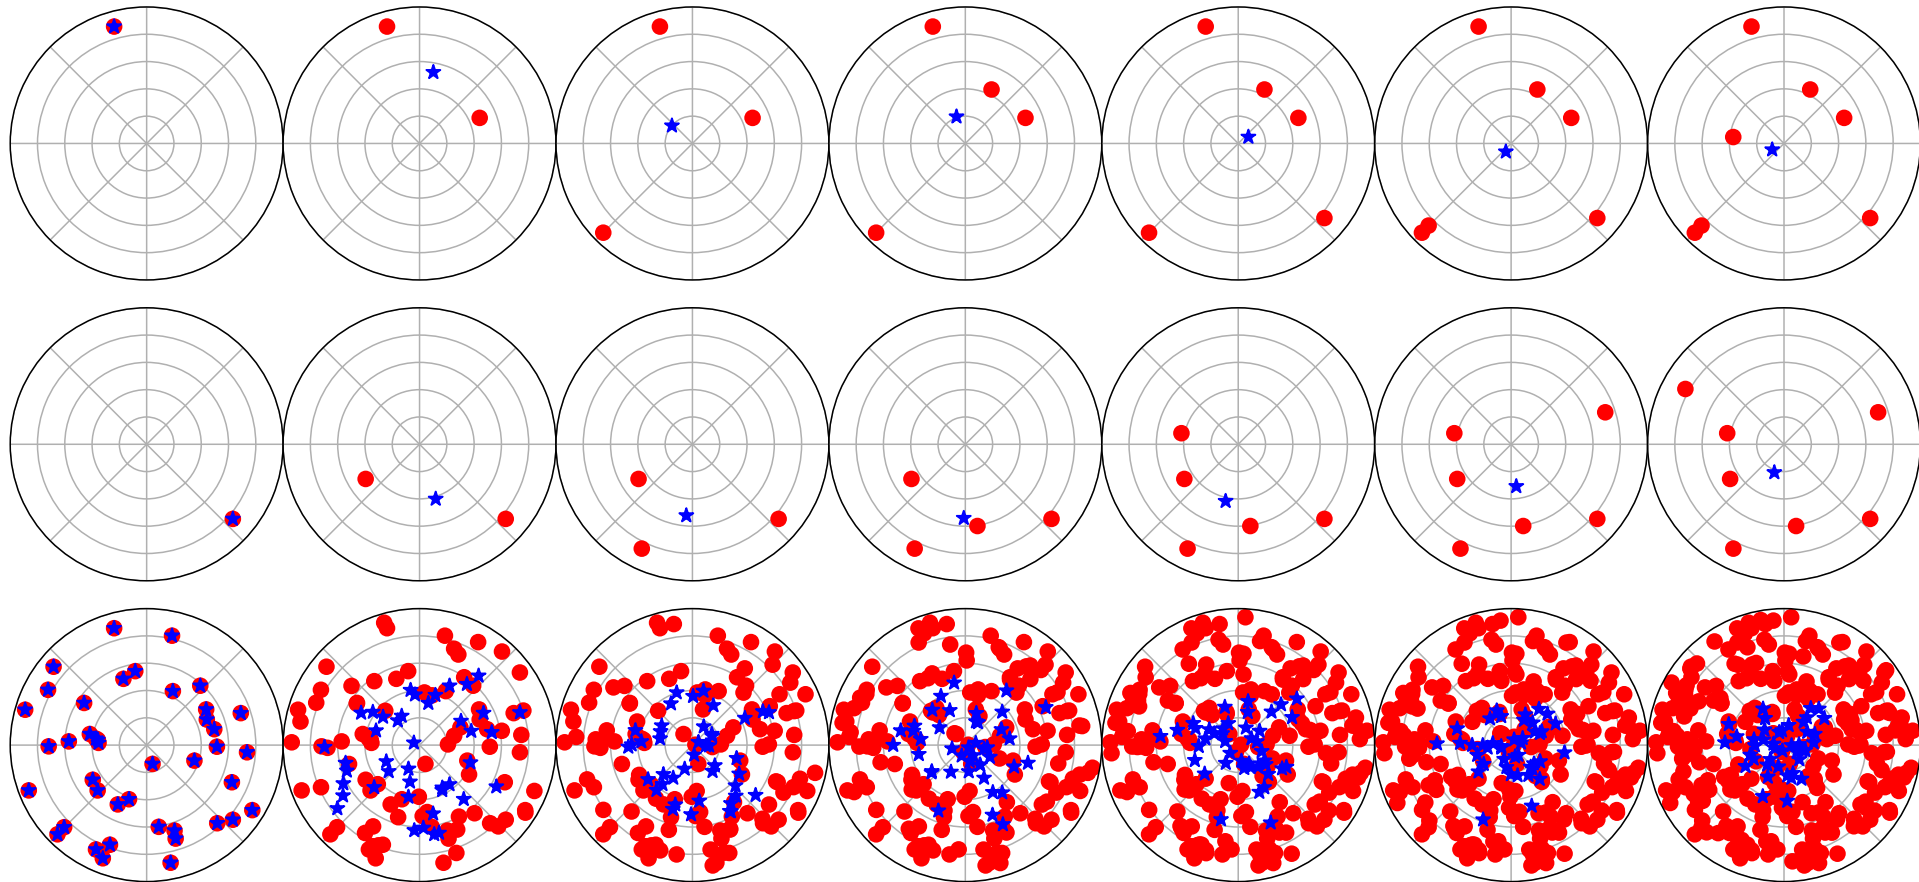

The terminology varies, but for classification:

- voting (or hard voting) usually means predicting the class predicted most often by the individual models,
- averaging (or soft voting) denotes averaging the returned model distributions and predicting the class with the highest probability.

The main idea behind ensembling is that if models have uncorrelated errors, then by averaging model predictions the errors will cancel out.

# Visualization of Ensembling Performance

Consider ensembling predictions generated uniformly on a planar disc:

# Model Combination aka Ensembling

If we denote the prediction of a model  $y_i$  on a training example  $(\mathbf{x}, t)$  as  $y_i(\mathbf{x}) = t + \varepsilon_i(\mathbf{x})$ , so that  $\varepsilon_i(\mathbf{x})$  is the model error on example  $\mathbf{x}$ , the mean square error of the model is

$$\mathbb{E}[(y_i(\mathbf{x}) - t)^2] = \mathbb{E}[\varepsilon_i^2(\mathbf{x})].$$

Considering  $M$  models, we analogously get that the mean square error of the ensemble is

$$\mathbb{E}\left[\left(\frac{1}{M} \sum_i \varepsilon_i(\mathbf{x})\right)^2\right].$$

Finally, assuming that the individual errors  $\varepsilon_i$  have zero mean and are *uncorrelated*, we get that  $\mathbb{E}[\varepsilon_i(\mathbf{x})\varepsilon_j(\mathbf{x})] = 0$  for  $i \neq j$ , and therefore,

$$\mathbb{E}\left[\left(\frac{1}{M} \sum_i \varepsilon_i(\mathbf{x})\right)^2\right] = \mathbb{E}\left[\frac{1}{M^2} \sum_{i,j} \varepsilon_i(\mathbf{x})\varepsilon_j(\mathbf{x})\right] = \frac{1}{M} \mathbb{E}\left[\frac{1}{M} \sum_i \varepsilon_i^2(\mathbf{x})\right],$$

so the average error of the ensemble is  $\frac{1}{M}$  times the average error of the individual models.

*ten ensembling má tedy ještě menší.*

*jak více měří jednotlivý model chybou*

# Bagging – Bootstrap Aggregation

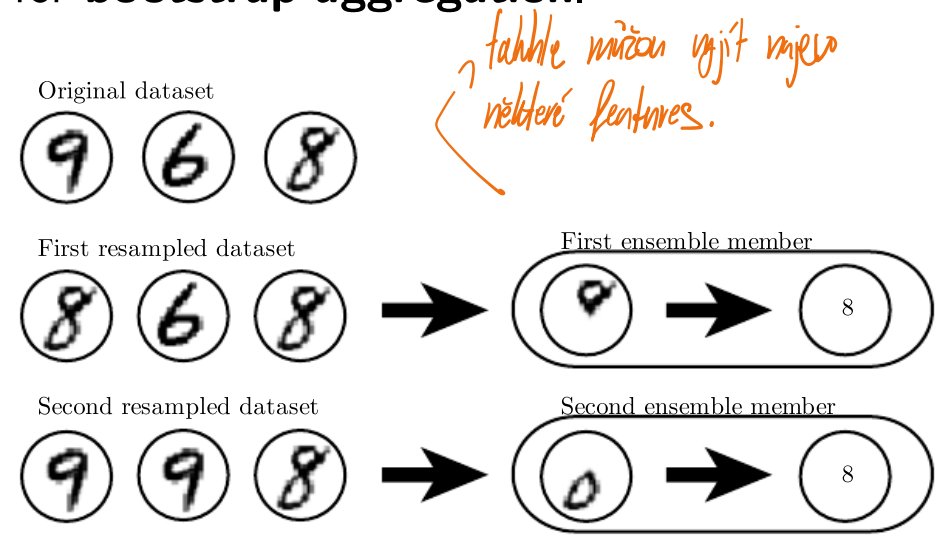

For neural network models, training models with independent random initialization is usually enough, given that the loss has many local minima, so the models tend to be quite independent just when using different random initialization.

However, algorithms with convex loss functions usually converge to the same optimum independent of randomization.

In these cases, we can use **bagging**, which stands for **bootstrap aggregation**.

In bagging, we construct a different dataset for every model to be trained. We construct it using **bootstrapping** – we sample as many training instances as the original dataset has, but **with replacement**.

Such dataset is sampled using the same empirical data distribution and has the same size, but is not identical.

*Musím těch modelů ale dělat dost, aby všechna data byla v nějakém modelu.*

Figure 7.5 of "Deep Learning" book, <https://www.deeplearningbook.org>

# Decision Trees

The idea of decision trees is to partition the input space into usually cuboid regions and solving each region with a simpler model.

We focus on **Classification and Regression Trees** (CART; Breiman et al., 1984), but there are additional variants like ID3, C4.5, ...

*Good practice je dělit podle jedné hodnoty*

Figure 14.6 of Pattern Recognition and Machine Learning.

Figure 14.5 of Pattern Recognition and Machine Learning.

*Dělení může být i složitější; pak se to ale blíže trénuje.*

# Regression Decision Trees

Assume we have an input dataset  $\mathbf{X} \in \mathbb{R}^{N \times D}$ ,  $\mathbf{t} \in \mathbb{R}^N$ . At the beginning, the decision tree is just a single node and all input examples belong to this node. We denote  $I_{\mathcal{T}}$  the set of training example indices belonging to a node  $\mathcal{T}$ .

For each leaf (a node without children), our model predicts the average of the training examples belonging to that leaf,  $\hat{t}_{\mathcal{T}} = \frac{1}{|I_{\mathcal{T}}|} \sum_{i \in I_{\mathcal{T}}} t_i$ . *- průměr dat, které skončí v tom listu*  
*↳ minimalizuje MSE*

We use a **criterion**  $c_{\mathcal{T}}$  telling us how *uniform* or *homogeneous* the training examples of a node  $\mathcal{T}$  are – for regression, we employ the sum of squares error between the examples belonging to the node and the predicted value in that node; this is proportional to the variance of the training examples belonging to the node  $\mathcal{T}$ , multiplied by the number of the examples. Note that even if it is not *mean squared error*, it is sometimes denoted as MSE.

$$c_{\text{SE}}(\mathcal{T}) \stackrel{\text{def}}{=} \sum_{i \in I_{\mathcal{T}}} (t_i - \hat{t}_{\mathcal{T}})^2, \text{ where } \hat{t}_{\mathcal{T}} = \frac{1}{|I_{\mathcal{T}}|} \sum_{i \in I_{\mathcal{T}}} t_i.$$

# Tree Construction

To split a node, the goal is to find a feature and its value such that when splitting a node  $\mathcal{T}$  into  $\mathcal{T}_L$  and  $\mathcal{T}_R$ , the resulting regions decrease the overall criterion value the most, i.e., the difference  $c_{\mathcal{T}_L} + c_{\mathcal{T}_R} - c_{\mathcal{T}}$  is the lowest.

*chci vybrat rozdělení, co bylo špatný. - chci to rozdělit tak, aby byly v listech co nejpodobnější data.*

We usually employ several constraints, the most common ones are:

- **maximum tree depth:** we do not split nodes with this depth;
- **minimum examples to split:** we only split nodes with this many training examples;
- **maximum number of leaf nodes:** we split until we reach the given number of leaves.

The tree is usually built in one of two ways:

- if the number of leaf nodes is unlimited, we usually build the tree in a depth-first manner, recursively splitting every leaf until one of the above constraints is invalidated;
- if the maximum number of leaf nodes is given, we usually split such leaf  $\mathcal{T}$  where the criterion difference  $c_{\mathcal{T}_L} + c_{\mathcal{T}_R} - c_{\mathcal{T}}$  is the lowest.

*Hraně jednoho se overf. týká, že udělám příliš větvi.*

To control overfitting, the previously-mentioned constraints can be used.

Additionally, **pruning** can also be used. After training, we might decide that some subtrees are not necessary, and *prune* them (replacing them with a leaf). Pruning can be used both as a regularization or model compression.

There are many heuristics to prune a decision tree; Scikit-learn implements **minimal cost-complexity pruning**:

- we extend the criterion to *cost-complexity criterion* as
  - for a leaf,  $c_\alpha(\mathcal{T}) = c(\mathcal{T}) + \alpha$ ,
  - for a subtree with a root  $t$ ,  $c_\alpha(t) = \sum_{\mathcal{T} \in \text{leaves}} c_\alpha(\mathcal{T}) = \sum_{\mathcal{T} \in \text{leaves}} c(\mathcal{T}) + \alpha|\text{leaves}|$ ;
- generally a criterion in a node  $t$  is greater or equal to the sum of criteria of its leaves;
- $\alpha_{\text{eff}}$  for a node  $t$  is the value of  $\alpha$  such that the two mentioned cost-complexity quantities ( $c_\alpha(\mathcal{T})$  computed as if  $t$  is a leaf, and  $c_\alpha(t)$ ) are equal
  - $\alpha_{\text{eff}} = (c(\mathcal{T}) - c(t)) / (|\text{leaves under } t| - 1)$ ;
- we then prune the nodes in the order of increasing  $\alpha_{\text{eff}}$ .

For multi-class classification, we predict the class which is the most frequent in the training examples belonging to a leaf  $\mathcal{T}$ .

To define the criteria, let us denote the average probability for class  $k$  in a region  $\mathcal{T}$  as  $p_{\mathcal{T}}(k)$ .

For classification trees, one of the following two criteria is usually used:

- **Gini index**, also called **Gini impurity**, measuring how often a randomly chosen element would be incorrectly labeled if it was randomly labeled according to  $\mathbf{p}_{\mathcal{T}}$ :

$$c_{\text{Gini}}(\mathcal{T}) \stackrel{\text{def}}{=} |I_{\mathcal{T}}| \sum_k p_{\mathcal{T}}(k)(1 - p_{\mathcal{T}}(k)),$$

- **Entropy Criterion**

$$c_{\text{entropy}}(\mathcal{T}) \stackrel{\text{def}}{=} |I_{\mathcal{T}}| \cdot H(\mathbf{p}_{\mathcal{T}}) = -|I_{\mathcal{T}}| \sum_{\substack{k \\ p_{\mathcal{T}}(k) \neq 0}} p_{\mathcal{T}}(k) \log p_{\mathcal{T}}(k).$$

# Binary Gini as (M)SE Loss

Recall that  $I_{\mathcal{T}}$  denotes the set of training example indices belonging to a leaf node  $\mathcal{T}$ , let  $n_{\mathcal{T}}(0)$  be the number of examples with target value 0,  $n_{\mathcal{T}}(1)$  be the number of examples with target value 1, and let  $p_{\mathcal{T}} = \frac{1}{|I_{\mathcal{T}}|} \sum_{i \in I_{\mathcal{T}}} t_i = \frac{n_{\mathcal{T}}(1)}{n_{\mathcal{T}}(0) + n_{\mathcal{T}}(1)}$ .

Consider sum of squares loss  $L(p) = \sum_{i \in I_{\mathcal{T}}} (p - t_i)^2$ .

By setting the derivative of the loss to zero, we get that the  $p$  minimizing the loss fulfills  $|I_{\mathcal{T}}|p = \sum_{i \in I_{\mathcal{T}}} t_i$ , i.e.,  $p = p_{\mathcal{T}}$ .

The value of the loss is then

$$\begin{aligned}
 L(p_{\mathcal{T}}) &= \sum_{i \in I_{\mathcal{T}}} (p_{\mathcal{T}} - t_i)^2 = n_{\mathcal{T}}(0)(p_{\mathcal{T}} - 0)^2 + n_{\mathcal{T}}(1)(p_{\mathcal{T}} - 1)^2 \\
 &= \frac{n_{\mathcal{T}}(0)n_{\mathcal{T}}(1)^2}{(n_{\mathcal{T}}(0) + n_{\mathcal{T}}(1))^2} + \frac{n_{\mathcal{T}}(1)n_{\mathcal{T}}(0)^2}{(n_{\mathcal{T}}(0) + n_{\mathcal{T}}(1))^2} = \frac{(n_{\mathcal{T}}(1) + n_{\mathcal{T}}(0))n_{\mathcal{T}}(0)n_{\mathcal{T}}(1)}{(n_{\mathcal{T}}(0) + n_{\mathcal{T}}(1))(n_{\mathcal{T}}(0) + n_{\mathcal{T}}(1))} \\
 &= (n_{\mathcal{T}}(0) + n_{\mathcal{T}}(1))(1 - p_{\mathcal{T}})p_{\mathcal{T}} = |I_{\mathcal{T}}| \cdot p_{\mathcal{T}}(1 - p_{\mathcal{T}}).
 \end{aligned}$$

# Entropy as NLL Loss

Again let  $I_{\mathcal{T}}$  denote the set of training example indices belonging to a leaf node  $\mathcal{T}$ , let  $n_{\mathcal{T}}(k)$  be the number of examples with target value  $k$ , and let  $p_{\mathcal{T}}(k) = \frac{1}{|I_{\mathcal{T}}|} \sum_{i \in I_{\mathcal{T}}} [t_i = k] = \frac{n_{\mathcal{T}}(k)}{|I_{\mathcal{T}}|}$ .

Consider a distribution  $\mathbf{p}$  on  $K$  classes and non-averaged NLL loss  $L(\mathbf{p}) = \sum_{i \in I_{\mathcal{T}}} -\log p_{t_i}$ .

By setting the derivative of the loss with respect to  $p_k$  to zero (using a Lagrangian with constraint  $\sum_k p_k = 1$ ), we get that the  $\mathbf{p}$  minimizing the loss fulfills  $p_k = p_{\mathcal{T}}(k)$ .

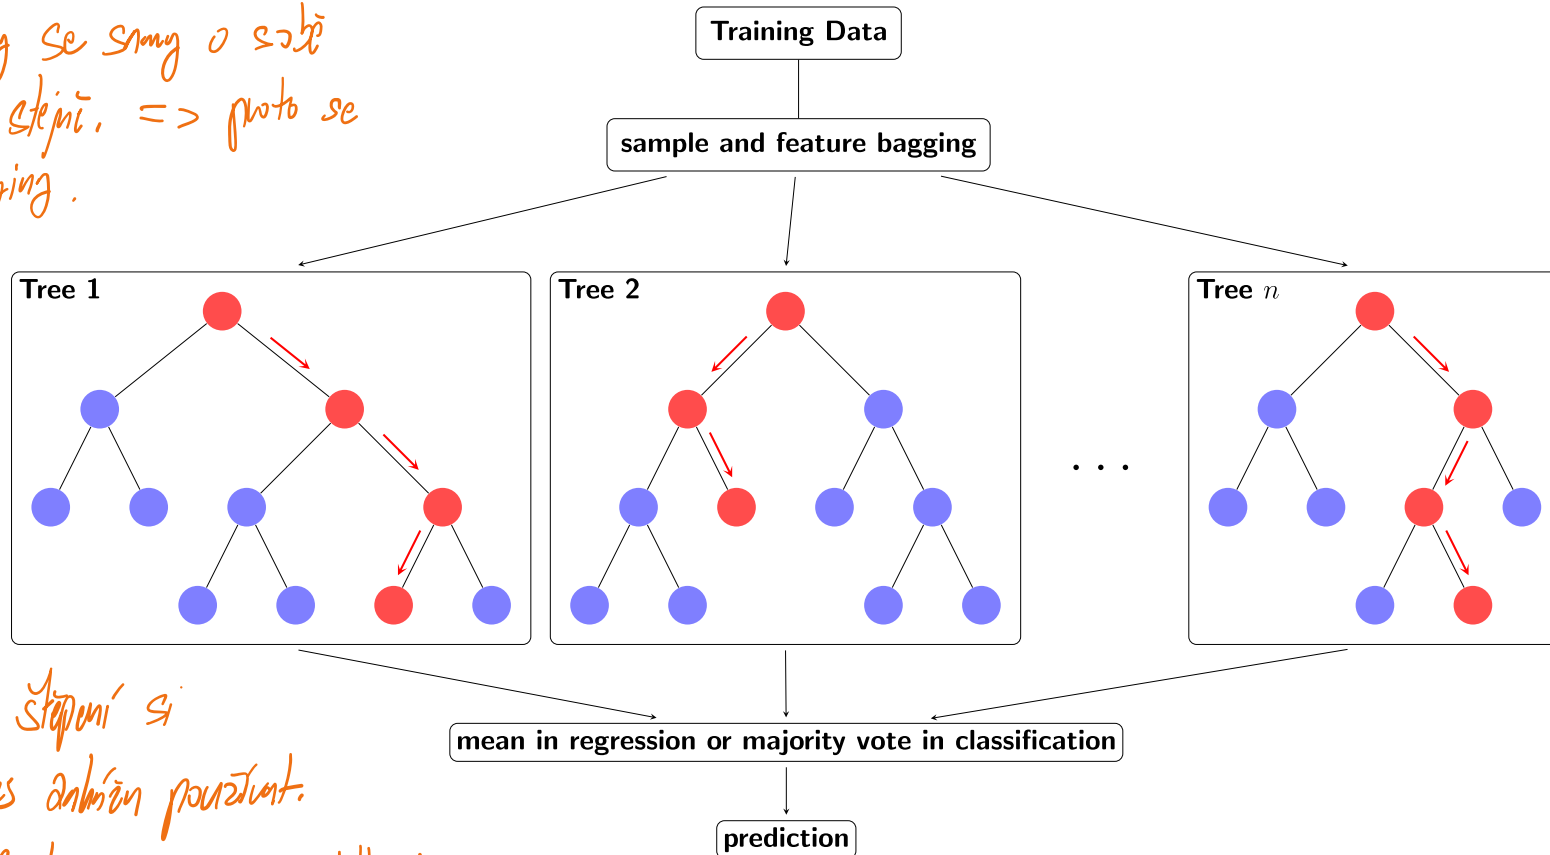

The value of the loss with respect to  $\mathbf{p}_{\mathcal{T}}$  is then  $n_{\mathcal{T}}(k) = p_{\mathcal{T}}(k) \cdot |I_{\mathcal{T}}|$

$$\begin{aligned}
 L(\mathbf{p}_{\mathcal{T}}) &= \sum_{i \in I_{\mathcal{T}}} -\log p_{t_i} \\
 &= - \sum_{\substack{k \\ p_{\mathcal{T}}(k) \neq 0}} n_{\mathcal{T}}(k) \log p_{\mathcal{T}}(k) \\
 &= -|I_{\mathcal{T}}| \sum_{\substack{k \\ p_{\mathcal{T}}(k) \neq 0}} p_{\mathcal{T}}(k) \log p_{\mathcal{T}}(k) = |I_{\mathcal{T}}| \cdot H(\mathbf{p}_{\mathcal{T}}).
 \end{aligned}$$

# Random Forests

Bagging of data combined with a random subset of features (sometimes called *feature bagging*).

*Ty stromy by se samy o sobě chovali úplně stejně. => proto se používá bagging.*

*Nebo v každém stupni si některé features odlišně používají.*

*— odlišnost featurem ve všech je blbost, jen někde je to chytrý, protože model bude hledat jiné příznaky.*

<https://tex.stackexchange.com/questions/503883/illustrating-the-random-forest-algorithm-in-tikz>

## Bagging

Every decision tree is trained using bagging (on a bootstrapped dataset).

## Random Subset of Features

During each node split, only a random subset of features is considered when finding the best split. A fresh random subset is used for every node.

## Extra Trees

The so-called extra trees are even more randomized, not finding the best possible feature value when choosing a split, but considering uniformly random samples from a feature's empirical range (minimum and maximum in the training data).

## Demo

<https://cs.stanford.edu/~karpathy/svmjs/demo/demoforest.html>
